AERONAUTICAL SYMBOLS

I. FUNDAMENTAL AND DERIVED UNITS

| Symbol | Metric | | English | |
|--------|---|--------|--|----------------------|
| | Unit | Symbol | Unit | Symbol |
| Length | meter | m | foot (or mile) | ft. (or mi.) |
| Time | second | sec | second (or hour) | sec. (or hr.) |
| Force | weight of one kilogram | kg | weight of one pound | lb. |
| Power | $\text{kg}/\text{m/sec}$ | | horsepower | H.P. |
| Speed | km/hr m/sec | | mi/hr ft/sec | M. P. H. f. p. s. |

2. GENERAL SYMBOLS, ETC.

| | |
|---|--|
| W , Weight, = mg | mk^2 , Moment of inertia (indicate axis of the radius of gyration, k , by proper subscript). |
| g , Standard acceleration of gravity = 9.80665 m/sec^2 = 32.1740 ft./sec. ² | |
| m , Mass, = $\frac{W}{g}$ | S , Area. |
| ρ , Density (mass per unit volume). Standard density of dry air, 0.12497 (kg-m^{-3}) at 15° C and 760 mm = 0.002378 (lb.-ft. ⁻³ sec. ⁻³). | S_w , Wing area, etc. |
| Specific weight of "standard" air, 1.2255 kg/m^3 = 0.07651 lb./ft. ³ | G , Gap. |
| | b , Span. |
| | c , Chord length. |
| | b/c , Aspect ratio. |
| | f , Distance from c. g. to elevator hinge. |
| | μ , Coefficient of viscosity. |

3. AERODYNAMICAL SYMBOLS

| | |
|--|---|
| V , True air speed. | γ , Dihedral angle. |
| q , Dynamic (or impact) pressure = $\frac{1}{2} \rho V^2$ | $\frac{Vl}{\mu}$, Reynolds Number, where l is a linear dimension. e.g., for a model airfoil 3 in. chord, 100 mi./hr. normal pressure, 0° C: 255,000 and at 15° C., 230,000; or for a model of 10 cm chord 40 m/sec, corresponding numbers are 299,000 and 270,000. |
| L , Lift, absolute coefficient $C_L = \frac{L}{qS}$ | C_p , Center of pressure coefficient (ratio of distance of C. P. from leading edge to chord length). |
| D , Drag, absolute coefficient $C_D = \frac{D}{qS}$ | β , Angle of stabilizer setting with reference to lower wing, = $(\alpha - \alpha_s)$. |
| C , Cross-wind force, absolute coefficient $C_C = \frac{C}{qS}$ | α , Angle of attack. |
| E , Resultant force. (Note that these coefficients are twice as large as the old coefficients I_C , D_C .) | ϵ , Angle of downwash. |
| Angle of setting of wings (relative to thrust line). | |
| Angle of stabilizer setting with reference to thrust line. | |

REPORT No. 317

WIND TUNNEL TESTS ON A SERIES OF WING MODELS THROUGH A LARGE ANGLE OF ATTACK RANGE

PART I. FORCE TESTS

By MONTGOMERY KNIGHT and CARL J. WENTZINGER

SUMMARY

This investigation covers force tests through a large range of angle of attack on a series of monoplane and biplane wing models. The tests were conducted in the atmospheric wind tunnel of the National Advisory Committee for Aeronautics. The models were arranged in such a manner as to make possible a determination of the effects of variations in tip shape, aspect ratio, flap setting, stagger, gap, decalage, sweep back, and airfoil profile. The arrangements represented most of the types of wing systems in use on modern airplanes.

The effect of each variable is illustrated by means of groups of curves. In addition, there are included approximate autorotational characteristics in the form of calculated ranges of "rotary instability."

A correction for blocking in this tunnel which applies to monoplanes at large angles of attack has been developed, and is given in an appendix.

INTRODUCTION

The need of greater safety in airplane flight leads to a consideration of the characteristics of wing systems at low speeds or large angles of attack. In general, the region of danger lies above the angle of maximum lift, and comparatively little information has been published relating to the landing, spinning, stability, and controllability of airplanes in this region.

In order to augment the information on this subject, a comprehensive test program is being carried out in the atmospheric wind tunnel at the Langley Memorial Aeronautical Laboratory. This program includes force, pressure distribution, and autorotation tests on a series of models representing most of the wing systems in use on modern airplanes. The angle of attack range of the tests is sufficiently large to cover practically all attitudes attainable by an airplane in flight.

The force test part of the program has been completed, and the results have already been published in part. (Reference 1.) The present report gives the complete information as to lift, drag, and resultant force, and also includes the calculated probable ranges of "rotary instability," an important phase of autorotation. With reference to rotation about a fixed axis in the plane of symmetry, and parallel to the wind direction, certain terms relating to autorotation are of importance, and may be defined as follows:

1. "Rotary instability" signifies a state of equilibrium in rectilinear motion such that rotations caused by small disturbances will increase in rate until a uniform angular velocity has been attained.

2. "Rotary stability" signifies a state of equilibrium in rectilinear motion such that rotations caused by small disturbances will decrease in rate until the angular velocity becomes zero.

3. "Neutral rotary equilibrium" signifies that state of equilibrium existing between the conditions of rotary stability and instability.

MODELS AND TESTS

The wing models which were constructed of laminated mahogany had a 5-inch chord and an aspect ratio of 6, except as noted in Tables I and II. The Clark Y profile was employed in all but a few of the tests in which the N. A. C. A. M-1 profile was used. With the exception of those tested to show tip effects, circular tipped models were used throughout.

The upper and lower wings of the biplane models were connected by means of two streamlined struts spaced 0.6 chord length apart, located along the span, 0.45 chord length from the leading edge and equidistant from the midspan. These struts fitted into sockets built into the wings. The sockets were designed so that the struts could be inclined in a fore and aft direction, and clamped rigidly in position. This arrangement, used in combination with struts of different lengths, made it possible to vary gap, stagger, and decalage as desired.

All of the force tests were conducted in the 5-foot atmospheric wind tunnel (Reference 2), which has a circular, closed-throat test section. The models were mounted in the wind tunnel on the usual wire balance as shown in Figure 1.

The tests were arranged to enable the determination of the effects produced by the variations in the wing models shown in Tables I and II. Lift, drag, and pitching moment were

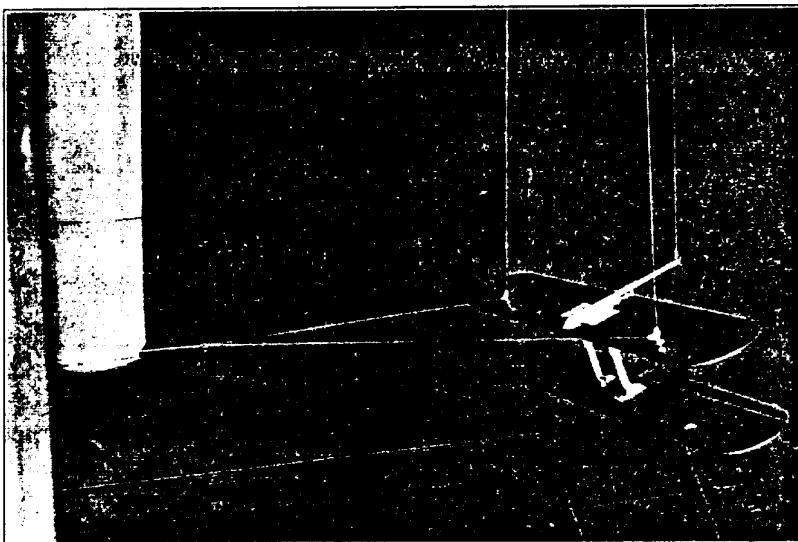

FIGURE 1.—Biplane set up in wind tunnel

measured for angles of attack ranging from -45° to $+90^\circ$. Due to the nature of the set-up, it was necessary for the complete test on each model to be made in three parts, the angle of attack range of one part overlapping by a few degrees that of the next.

The tests were conducted at an average dynamic pressure of 19.93 kg. per m^2 corresponding to an average air speed of 17.9 meters per second (40.0 M. P. H.), and an average Reynolds Number of 153,000.

All drag readings were corrected for the drag of the supporting system. The biplane strut drag was found to be negligible, and was therefore disregarded.

The test results are not corrected for tunnel wall interference for the following reasons:

a. The Prandtl correction for tunnel wall interference effects on the wing-tip vortices is known to be accurate only up to maximum lift. In general, it appears that at about 25° angle of attack this correction becomes negligible. However, between the angle of maximum lift and 25° the amount of the correction is not known, and in consequence it has been omitted.

b. At approximately 25° the blocking of the air flow by the model causes an increase in effective dynamic pressure in the region of the model. This effect reaches a maximum at an

¹ Stagger measured at midspan.

angle of attack of about 90° for a given wing. Tests have been made from which a correction for blocking has been derived, and the results are given in the appendix. This correction, however, applies to monoplanes only, and hence it has not been used in this report, which covers biplanes as well as monoplanes. The determination of the blocking corrections for biplane wings is a problem which requires further research.

The lift, drag, and pitching moment were measured in general to within an accuracy of ± 1.5 per cent. In the construction of the wing models the tolerance with reference to the airfoil ordinates was ± 0.003 inch.

RESULTS

For purposes of direct comparison, the test results are presented in groups of curves and diagrams, each group showing the effects of one of the variables as listed in Tables I and II. These groups, given in Figures 2 to 52, are arranged for each variable in four consecutive sections as follows:

- (a) Absolute lift and drag coefficients vs. angle of attack (C_L and C_D vs. α).
- (b) Polars (C_L vs. C_D).
- (c) Center of pressure coefficients vs. angle of attack (C_p vs. α).
- (d) Vector diagrams.

In the center of pressure curves for the monoplanes, the plotted points represent the intersection of the resultant force vectors with the wing chord line. Similarly, the "mean chord" (halfway between the chords of the upper and lower wings as indicated on the vector diagrams) of the biplane models was used in obtaining the C_p values. It should be borne in mind that the C_p curves illustrated hold good only for the base lines assumed, and that any other reference lines would give different results.

Lift and drag coefficients and angle of attack for each complete force test are given in Tables IV to XXVII, inclusive.

The calculated probable ranges of "rotary instability" for each model tested are indicated in Table III. These ranges were obtained by noting the points on the polar curves at which radial lines through the origin were perpendicular to the curves. Each point of intersection signifies a state of "neutral rotary equilibrium," as previously defined, and is shown as such on the comparative polar curve groups. Then where the slope of the curve is negative between these points with respect to the radial lines, the wing model will be capable of autorotation, i. e., will be in a state of "rotary instability." The negative slope indicates a decreasing resultant force with increasing angle of attack, and this is the criterion for "rotary instability," which may be expressed as—

$$\frac{d(C_R)}{d\alpha} < 0$$

(See Reference 3 for derivation), where C_R is the absolute coefficient of resultant force, and α is the angle of attack of the wing. This criterion, however, is an approximation, subject to the limitations of the "strip method" of autorotation calculation, which assumes a uniform distribution of the resultant force along the span, for the wing in rectilinear motion.

DISCUSSION OF RESULTS

A general survey of the curves and diagrams demonstrates the appreciable effects which changes in the geometry of wing systems have on lift, drag, and center of pressure, particularly at large angles of attack. It will be noted that the effect on drag is the most marked, and the influence of stagger is greater than that of gap or decalage. The effects of variations in stagger, gap, and sweep back, at the large angles of attack, are largely due to the partial shielding of the biplane upper wing by the lower. (Reference 4.)

Referring now to the curves in greater detail, the effects of the variables on the aerodynamic characteristics of the wing models may be listed as follows:

MONOPLANES

1. TIPS

LIFT (figs. 2, 3):

Maximum C_L is highest for rectangular tips, next for negative raked tips, and lowest for the circular tips, although the difference is small.

DRAG (figs. 2, 3):

Minimum C_D shows little difference, and in general C_D is much the same for the three models with different tip shapes.

CENTER OF PRESSURE (figs. 4, 5, 6, 7):

The C_p curves show little variation for the three different tips, and the differences may be explained as due to the different dispositions of the wing area.

2. ASPECT RATIO

LIFT (figs. 8, 9):

Maximum C_L increases with increase of aspect ratio. The slope of the lift curve below maximum C_L becomes greater due to the decrease in the induced angle of attack. This decrease is also partly due to tunnel wall interference.

DRAG (figs. 8, 9):

Minimum C_D is practically the same for the aspect ratios investigated. The effects of aspect ratio and the tunnel walls on induced drag are apparent below maximum lift. Above 20° angle of attack, C_D increases in the order of the aspect ratio and the differences are due in great measure to blocking effects at large angles.

CENTER OF PRESSURE (figs. 7, 10, 11, 12):

The C_p curves for the different aspect ratios covered in the tests are practically the same.

3. FLAP

LIFT (figs. 13, 14):

Maximum C_L increases with increasing flap angle in the downward direction, and occurs at slightly lower angles of attack. Moving the flap downward through a given angle increases the lift by an amount approximately equal to the decrease produced by moving it up through the same angle. It will be noted that in Figure 13, just beyond each of the primary and secondary lift peaks the changes in lift are small.

DRAG (figs. 13, 14):

Above zero angle of attack the drag increases in a regular manner, both with increasing angle of attack and with flap moving from up to down postions.

CENTER OF PRESSURE (figs. 7, 15, 16, 17, 18, 19):

For angles of attack above zero lift the C_p travel becomes smaller with decreasing flap angle, due to the decrease of the effective camber of the wing. With the flap displaced upward 15°, the travel is backward above zero lift. For flap settings of from 15° to 30° down, the C_p curves are much the same above zero lift, but are displaced to the rear with respect to the neutral flap curve. Attention is called to the marked difference in the shape of the curves for the 15° upward and downward flap displacements below zero lift.

4. PROFILE

LIFT (figs. 20, 21):

Maximum C_L is much higher for the Clark Y than for the symmetrical N. A. C. A.-M1. The angle of zero lift is higher for the N. A. C. A.-M1, due to its straight mean camber line.

DRAG (figs. 20, 21):

From -3° to +8°, the drag of the N. A. C. A.-M1 is less than that for the Clark Y, and is greater from +8° to 18°. Above 18°, and below -3°, C_D for the N. A. C. A.-M1 is the lower.

CENTER OF PRESSURE (figs. 7, 22, 23):

The *C. P.* travel for the N. A. C. A.-M1 is practically negligible from -6° to $+6^\circ$ angle of attack, and then moves rearward. The Clark Y, however, has a forward motion of *C. P.* up to 12° angle of attack, and rearward beyond this angle.

BIPLANES**5. STAGGER****LIFT (figs. 24, 25):**

Maximum C_L increases with increase of stagger up to +25 per cent and then remains the same for 50 per cent stagger, although occurring at a slightly smaller angle of attack.

DRAG (figs. 24, 25):

Minimum C_D is highest for the zero stagger. Above the angle of maximum C_L , however, C_D increases greatly with increase in stagger. These effects on drag at the large angles of attack are due mainly to the partial shielding of the upper wing of the biplanes by the lower.

CENTER OF PRESSURE (figs. 26, 27, 28, 29, 30):

The distance traveled back by the *C. P.* above maximum C_L becomes greater with increasing stagger. The peculiar behavior of negative stagger at large angles of attack should be noted.

6. GAP**LIFT (figs. 31, 32):**

Maximum C_L increases up to G/c ratio of 1.0 where it appears to remain constant for G/c ratio increase, although the slope of the lift curve becomes greater with higher G/c ratios. This is due to the decrease in induced angle of attack with increasing gap.

DRAG (figs. 31, 32):

Minimum C_D is approximately the same for the G/c ratios tested. For the large angles of attack, C_D increases with increasing G/c ratios.

CENTER OF PRESSURE (figs. 28, 33, 34, 35):

As the G/c ratio is increased, the *C. P.* above maximum lift recedes farther with increase of angle of attack up to 50° , although not as far as for the staggered biplanes.

7. DECALAGE**LIFT (figs. 36, 37):**

Positive and negative decalage cause a lower maximum C_L than zero decalage, but the magnitude is about the same for the same values of decalage, plus or minus. For positive decalage, maximum C_L occurs at a smaller angle of attack, and that of negative decalage at a larger angle than that for zero decalage.

It can also be seen that the lift and drag curves for positive or negative decalage are shifted by an approximately constant angle to one or the other side of those for zero decalage. Since the lower wing of the biplane was set at $\pm 3^\circ$ with respect to the upper wing at zero lift, the "effective" angle of attack becomes respectively 1.5° minus or plus the angle of attack of zero lift for no decalage.

DRAG (figs. 36, 37):

Maximum C_D shows little difference for the angles of decalage investigated, but C_D increases with increase of decalage.

CENTER OF PRESSURE (figs. 28, 38, 39, 40):

Negative decalage causes a more rapid recession of the *C. P.* above maximum C_L , with increase of angle of attack, than does either zero or positive decalage. The sharp peak on the -3° curve is remarkable.

The effects of decalage are not as great as those produced by stagger, but they are greater than those due to changes in gap.

8. SWEEP BACK

LIFT (figs. 41, 42):

Maximum C_L occurs at about the same angle of attack for all conditions tested. C_L is highest for +50 per cent stagger at midspan with the upper wing swept back, and lowest for the same combination with zero stagger.

The similarity is very striking between the lift curves of the two combinations with upper wing swept back, +50 per cent midspan stagger, and lower wing swept back, zero stagger. The other two combinations tested are also very similar, and this indicates that sweep back in one wing is, effectively, stagger. No appreciable difference is shown whether the stagger used with the swept-back wing is at the tips or at midspan.

DRAG (figs. 41, 42):

The similarity between the drag curves of the same pairs of combinations as noted in the case of lift, is very noticeable, and also indicates that sweep back in one wing is, in effect, stagger.

CENTER OF PRESSURE (figs. 43, 44, 45, 46, 47):

The most noticeable effect brought out by the C_p curves is the fairly close resemblance between the results for the biplane with upper wing swept back, zero midspan stagger, and that with the lower wing swept back, -50 per cent midspan stagger.

9. PROFILE

LIFT (figs. 49, 50):

The N. A. C. A.-M 1 in combination with the Clark Y gives a lower maximum C_L than with both wings Clark Y, and the lift curves have more rounded peaks.

DRAG (figs. 49, 50):

Minimum C_D is slightly lower for the combination of N. A. C. A.-M1 wing lower and Clark Y upper. In general, with both wings Clark Y, the drag is slightly higher at large angles of attack.

CENTER OF PRESSURE (figs. 28, 48, 51, 52):

The C_p curves for the three combinations tested do not show any great variations. The combination of the N. A. C. A.-M1 lower wing and Clark Y upper wing is probably the most desirable from the standpoint of safety, due to the smaller slope of the curve in the region of the angle of maximum C_L , which means less instability longitudinally.

10. ROTARY INSTABILITY

From a consideration of the calculated ranges of rotary instability (Table III), the following points may be noted:

None of the monoplanes show any tendency toward autorotation above 26°, but the biplanes indicate additional autorotational tendencies above this angle.

Positive stagger is seen to reduce the tendency of the biplanes to autorotate at the large angles, while increase in gap within practical limits has a similar effect, only to a smaller degree.

Sweep back arranged so as to give positive stagger at the tips appears to reduce the range of rotary instability at large angles of attack. Geometrically, sweep back in one wing of a biplane is merely a progressive change in stagger along the span. The criterion for rotary instability is based on the assumption of uniform span loading, and for this reason the points of neutral rotary equilibrium are only roughly approximate for the swept-back wing combinations.

Decalage seems to have no appreciable effect in reducing the rotary instability ranges of the biplanes.

CONCLUSIONS

Since these force tests have been made at the low Reynolds Number of 153,000, any conclusions as to the effects of the variable factors should be drawn with that in mind. As the effects at angles of attack below maximum lift have already been fully investigated, the conclusions given here apply to the results at maximum C_L and above.

MONOPLANES

1. TIPS.—Different shaped tips produce only small effects.
2. ASPECT RATIO.—Increase of aspect ratio slightly increases maximum C_L , and C_D also increases at large angles.
3. FLAP.—Moving the flap down increases maximum C_L which occurs at slightly lower angles of attack. C_D also increases with downward movement of the flap.
4. PROFILE.—The Clark Y has a much higher maximum C_L than the N. A. C. A.-M1.

BIPLANES

5. STAGGER.—Increase in stagger raises the maximum C_L , and greatly increases C_D above the angle of maximum lift.
6. GAP.—Larger gap slightly increases the maximum C_L , and causes an increase in C_D , although the effects are not as great as those of stagger.
7. DECALAGE.—Positive and negative decalage have very little effect except to shift the lift and drag curves as a whole to one side or the other of those for zero decalage.
8. SWEEP BACK.—Sweep back may be considered as a form of stagger, since the result of combining a swept-back wing with a straight wing in a biplane is similar to staggering a straight wing biplane.
9. PROFILE.—The N. A. C. A.-M1 wing in combination with the Clark Y gives lower maximum C_L than with both wings Clark Y, and the lift curve peaks are more rounded.
10. ROTARY INSTABILITY.—The autorotational characteristics of wing systems are greatly affected by changes in profile and in the geometrical arrangement of the wings.

APPENDIX

By Thomas A. Harris

In the force tests described in the foregoing report, the dynamic pressure was maintained constant at the position of the "service Pitot." (Fig. 53.) This dynamic pressure q' , is a certain fraction of the dynamic pressure q , at the position of the model (with model removed from the tunnel), several feet downstream with the honeycomb between it and the "service Pitot." (Fig. 53.) In order to determine the relation between q' and q , a Pitot-static survey was conducted at the position of the model, and the "service Pitot" was then calibrated against this survey.

Since this wind tunnel is of the closed throat test section type, if part of the test section is blocked by a model, the same amount of air must pass through the restricted area that formerly passed through the unobstructed section. With the model at small angles of attack, the blocked area is small, but at large angles the blocking causes the dynamic pressure q'' , at the position of the model, to increase appreciably, while it does not affect the dynamic pressure q' , at the "service Pitot." The variable dynamic pressure q'' , is the value from which the absolute coefficients should be calculated. In the tests described in the foregoing report, however, the absolute coefficients C_D and C_L (uncorrected for blocking), were calculated from values of q . Since q is less than q'' , these coefficients are higher than C'_D and C'_L (corrected for blocking).

TESTS

To determine the blocking correction, force tests were made on a series of rectangular "flat" plates, with 3, 4, 5, 6, and 7 inch chords, and of aspect ratio 6. The upstream surface of each plate was flat, while the downstream surface was pyramidal in form, beveled 15° from all edges. These flat plates were used instead of airfoils because they were more easily constructed, and answered the same purpose.

The force tests on these plates were made on the regular wire balance of the wind tunnel. (Reference 2.) Lift and drag data were obtained for angles of attack ranging from 20° to 90°, and the absolute coefficients (C_D and C_L) were then calculated. All tests were run at an average Reynolds Number of 153,000, the chord length being taken as the characteristic dimension.

RESULTS

The results of the force tests on the flat plates are given in Table XXIX, and as curves in Figures 57a and 58a. C_D was also plotted against the areas of the flat plates for the various angles of attack (Figure 54). These curves were extrapolated to zero area (as shown by the broken lines), to obtain C'_D the absolute free air coefficient.

From the curves (fig. 54) it can readily be seen that:

$$C'_D = KC_D \quad (1)$$

from which it follows that

$$K = \frac{C'_D}{C_D} \quad (2)$$

Values of K were calculated for the several plates at the various angles of attack by means of equation (2), and by data obtained from the curves. (Fig. 54.) It is apparent that K is a function of the area ratio (a/A), where a is the projected area of the model perpendicular to the air stream, and A is the cross-sectional area of the tunnel at the test section. Values of (a/A)

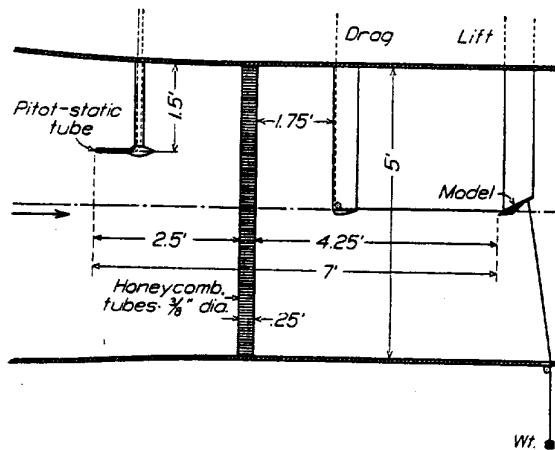

FIGURE 53.—Blocking tests. Wind tunnel set-up

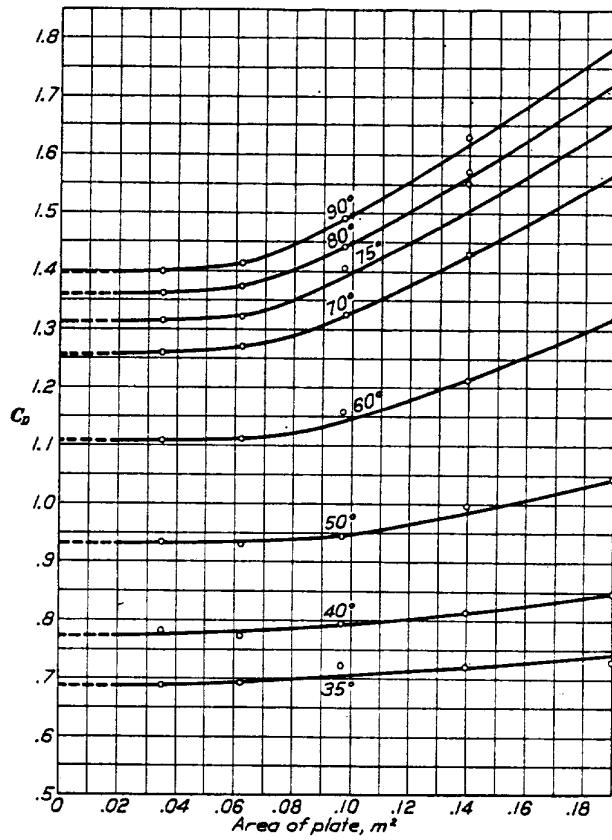

FIGURE 54.—Drag versus area of plate

with the corresponding values of K are given in Table XXVIII, and are plotted in logarithmic form in Figure 55. It was found that a straight line could be drawn through these points, with a maximum deviation of about 2 per cent.

From an analysis of this line it was found that:

$$K = 1 - 6.75 (a/A)^{2.4} \quad (3)$$

This equation was plotted on regular cross-section paper (Figure 56) to be used in finding corrections for C_D and C_L for any value of area ratio up to about 0.08. The area ratios of the 7-inch chord flat plate exceeded this value and the curve of the equation would not pass through these points. A broken line is, however, faired through them.

As (a/A) increases, q'' also increases while q' is kept constant. Therefore the lift and drag are both affected and the same correction applies to each. C_D was used for determining the blocking correction because as the angle of attack increases, C_D increases, while C_L decreases,

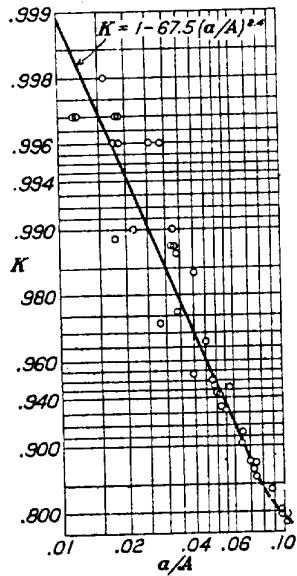

FIGURE 55.—Blocking correction versus area ratio (logarithmic)

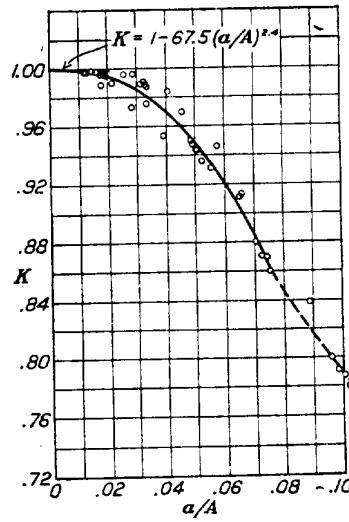

FIGURE 56.—Blocking correction versus area ratio

and for large angles of attack the experimental error becomes a larger percentage of the C_L results.

By use of equation (3) the flat plate data for chord lengths 3, 4, 5, and 6 inches were corrected. The values of C_D , C_L , $C_{D'}$, and $C_{L'}$ are given in Table XXIX, and are plotted in Figures 57 a and b, and 58 a and b, as absolute coefficients vs. angle of attack, and as polars. The corrected points are within the experimental error of the force test results for the flat plates. The limit of (a/A) for the flat plate tests was about 0.10. This value is safely beyond any value of (a/A) used in the series of wing model tests.

To verify formula (3), the correction was applied to the data obtained from force tests on two circular tipped Clark Y airfoils, of aspect ratio 8, with 3 and 5 inch chords. These data are given in Table XXX and are plotted in Figures 59 a and b, and 60 a and b, as absolute coefficients vs. angle of attack, and as polars. The corrected values of C_D and C_L for the airfoils are, in general, within 1 per cent of the faired curves, which is within the experimental error of the force tests.

CONCLUSIONS

1. A blocking correction curve for monoplane test results has been obtained which applies to this wind tunnel for ratios of projected area of the model to cross-sectional area of the tunnel up to about 0.10.

2. Further research is necessary to obtain a similar correction for biplane test results at large angles of attack.

3. It is highly desirable that some means be devised for maintaining the dynamic pressure constant in the vicinity of the model, regardless of the change in angle of attack, above maximum lift.

LANGLEY MEMORIAL AERONAUTICAL LABORATORY,
NATIONAL ADVISORY COMMITTEE FOR AERONAUTICS,
LANGLEY FIELD, V.A., July 31, 1928.

Positive directions of axes and angles (forces and moments) are shown by arrows

| Axis | | Force (parallel to axis) symbol | Moment about axis | | Angle | | Velocities | | |
|--------------|--------|--|-------------------|--------|-----------------------|------------------|------------|--|---------|
| Designation | Symbol | | Designa- tion | Symbol | Positive direction | Designa- tion | Symbol | Linear (compo- nent along axis) | Angular |
| Longitudinal | X | X | rolling | L | $Y \rightarrow Z$ | roll | ϕ | u | p |
| Lateral | Y | Y | pitching | M | $Z \rightarrow X$ | pitch | θ | v | q |
| Normal | Z | Z | yawing | N | $X \rightarrow Y$ | yaw | ψ | w | r |

Absolute coefficients of moment

$$C_L = \frac{L}{qbS}, C_M = \frac{M}{qcS}, C_N = \frac{N}{qfS}$$

Angle of set of control surface (relative to neutral position), δ . (Indicate surface by proper subscript.)

4. PROPELLER SYMBOLS

- D , Diameter.
 p_e , Effective pitch
 p_g , Mean geometric pitch.
 p_s , Standard pitch.
 p_0 , Zero thrust.
 p_a , Zero torque.
 p/D , Pitch ratio.
 V' , Inflow velocity.
 V_s , Slip stream velocity.

- T , Thrust.
 Q , Torque.
 P , Power.
 (If "coefficients" are introduced all units used must be consistent.)
 η , Efficiency = $T V/P$.
 n , Revolutions per sec., r. p. s.
 N , Revolutions per minute., R. P. M.
 Φ , Effective helix angle = $\tan^{-1} \left(\frac{V}{2\pi n} \right)$

5. NUMERICAL RELATIONS

- 1 HP = 76.04 kg/m/sec. = 550 lb./ft./sec.
 1 kg/m/sec. = 0.01315 HP.
 1 mi./hr. = 0.44704 m/sec.
 1 m/sec. = 2.23693 mi/hr.

- 1 lb. = 0.4535924277 kg.
 1 kg = 2.2046224 lb.
 1 mi. = 1609.35 m = 5280 ft.
 1 m = 3.2808333 ft.
